Project Background Applied principles Variety of settings

#### Part II Merging of advices

#### Part III

Software implementation

▲□▶ ▲□▶ ▲ □▶ ▲ □▶ □ のへぐ

### Problem formulation

#### 18 models

```
system model - static / dynamic
 user target - maximum / moving average / estimated
 design method - academic / industrial / simultaneous
```

- Data were recorded in 6 month, i.e. many different working conditions.
- > The operator **did not** follow the advices.
- The designed advisers are not directly comparable (missing variances).

▶ We seek an external measure of quality of advising.

## Possible approaches

- 1. Strictly scientific experiment:
  - test all methods under exactly the same conditions.
  - impossible in production line in a factory.
- 2. Detailed modeling:
  - model discrepancy between the observed data and observation that would be observed if the operator followed our recommendation.
  - too much uncertainty to be modeled.
- 3. High-level black-box modeling
  - we build a simple auto-regressive model of the relation between two key quantities:

▲□▶ ▲□▶ ▲□▶ ▲□▶ ■ ● ●

- a) closeness, C, of recommendations to true actions,
- b) quality of operator performance, P.

## High-level model

- From a full set of 40 variables we pick two: input deviation, h<sub>1</sub>, and output deviation, h<sub>2</sub>.
- Large data-records are split into blocks of 1000 samples.
- Operator performance index for one block:

$$P=\frac{\mathsf{E}(h_2^2)}{\mathsf{E}((h_1-\overline{h_1})^2)},$$

E denotes empirical expected value on the block of data.

Closeness of advices:

$$C_{i,t} = E\left(1 - \frac{\max\left(|u_t - u_{i,t}^{\star}|, u_t\right)}{u_t}\right),$$

 $u_{i,t}^{\star}$  is the recommended action of the *i*th adviser, and  $u_t$  is the actual realization.

• Lets assume that  $P_t$  is related to  $C_i$  via an unknown function,  $P_t = g_i(C_i).$ 

## High-level model

• Lets assume that  $P_t$  is related to  $C_i$  via an unknown function,

$$P_t = g_i(C_i).$$

• Taylor expansion at operating point  $\overline{C}_{i,t}$  at time t yields

$$P_t = g_i(\overline{C}_{i,t}) + g'_i(\overline{C}_{i,t})(C_{i,t} - \overline{C}_{i,t}) + e_t, \qquad (1)$$

where  $g'_i()$  denotes the first derivative of  $g_i()$ ,  $\overline{C}_{i,t}$  is the fixed point of expansion, and  $e_t$  is an aggregation of higher order term.

**Model:** motivated by (1)

$$P_t = b_{i,t} + a_{i,t}C_{i,t} + \sigma_{i,t}v_t, \qquad (2)$$

where  $b_{i,t}$ ,  $a_{i,t}$ ,  $\sigma_{i,t}$  are unknown time-variant parameters.  $v_t \sim \mathcal{N}(0,1)$  is Gaussian noise.

- time-variant parameters accommodate for time-varying expansion point, allowing fitting of the linearization to the current situation.
- ▶ Model (2) can be estimated exactly using Bayesian theory.

# Merging of advices

Task:

Recommend an action, which if followed would lead to the highest operator's performance.

▲□▶ ▲□▶ ▲□▶ ▲□▶ ▲□ ● ● ●

- Decision-making problem.
- Operator's performance is modeled by the high-level models.

# Merging of advices

Task:

Recommend an action, which if followed would lead to the highest operator's performance.

- Decision-making problem.
- Operator's performance is modeled by the high-level models.
  Formally:

$$u_{t+1}^{\text{mer}} = \arg\min_{u_t} E(P_{t+1}|u_{t+1}).$$
$$E(P_{t+1}|u_{t+1}) = \sum_{i=1}^{18} \alpha_{i,t} f(P_{t+1}|C_{i,t+1}(u_{t+1})),$$
$$\alpha_{i,t} = f(i_t = i|P_t, C_t) \propto f(P_t|C_{i,t}, i).$$

▲□▶ ▲□▶ ▲□▶ ▲□▶ ▲□ ● ● ●

#### Approximate merging

Evaluation of the formal problem is computationally prohibitive. We tested the following approximation:

1. winner takes all.

$$lpha_{i,t} pprox [0, \dots, 1, \dots 0].$$
  
 $\hat{i} = rg\max f(P_t | C_{i,t}, i).$ 

(Choosing just one component from the mixture).

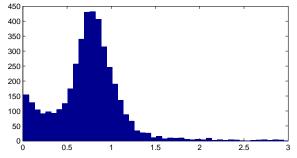

2. Avoiding optimization of  $C_{i,t}(u_t)$ . Each adviser has already designed its optimal strategy  $u_{i,t}^{(o)}$ , i.e.

$$u_{t+1}^{\text{mer}} = \arg\min_{u_t} E(P_{t+1}|u_{t+1}).$$
  
 $\approx u_{\hat{i},t+1}^{(o)}.$

## Data for the experiment

- Data set collected during 6 month of production of a cold rolling mill,
- ▶ more than 4,2 million of 10 dimensional data records,
- The set contains data from a wide range of operating condition such as different materials or different passes though the mill.
- The quality of final product was within the required range for great majority of the data, and so was the operator's performance index:

This implies that the AGC low-level controllers worked very well, leaving only a narrow margin for improvement.

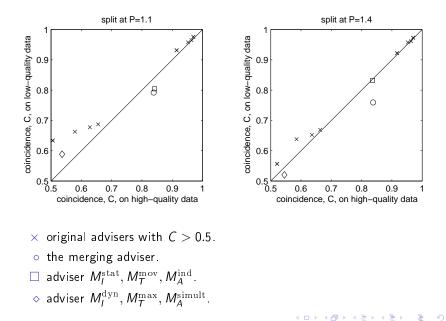

#### Experimental results

- Both operator's performance index and coincidence was computed for each model for each of the 4227 data batches.
- Scatter plots of these quantities form irregular clusters, discouraging visual inspection and parametric modeling of the relation.
- Hence, we propose to choose a threshold P̂ of 'good' performance and split all data records in two sets:
  - high-quality data,  $P < \hat{P}$ ,
  - low-quality data,  $P \ge \hat{P}$ .
- The rationale is that good adviser should recommend actions that are:

- close to the actual actions when the performance is good,
- far from the actual actions when the performance is bad.

### Experimental results

# Part II Summary

- High-level black-box model was chosen as a representation of quality of advising.
- > Parameters of the model were estimated using Bayesian theory.
- Merging of advices was formulated as an optimization problem under uncertainty, which was further approximated.

▲□▶ ▲□▶ ▲□▶ ▲□▶ ▲□ ● ● ●

 The resulting algorithm is relatively robust to tuning knobs in the choice evaluation criteria.
